Abstract

AutoCorres2 is a tool to facilitate the verification of C programs within Isabelle [5]. It is a fork of AutoCorres.

Contents

Chapter 1

Introduction

AutoCorres2 is a tool to facilitate the verification of C programs within Isabelle [5]. It is a fork of AutoCorres: https://trustworthy.systems/projects/OLD/autocorres/. Here some quick links into the document:

- Quickstart guide for users (chapter 25): `doc/quickstart/Chapter1_MinMax.thy`
- Background information, internals and some history of AutoCorres (chapter 26): `doc/AutoCorresInfrastructure.thy`
- C-Parser
  - Some internals (chapter 27): `c-parser/CTranslationInfrastructure.thy`
  - Original documentation (outdated) (chapter 28): The supported subset of C is extended. Moreover, the C-parser is integrated into Isabelle/ML and no standalone C-parser is supplied. The description of the design principles is still valid: `c-parser/doc/ctranslation_body.tex`

A combinator for pairing up well-formed relations. The divisor function splits the population in halves, with the True half greater than the False half, and the supplied relations control the order within the halves.

ML Antiquotations

3.1 Building terms: *mk-term*

theory *MkTermAntiquote*
imports
Pure
begin

mk-term: ML antiquotation for building and splicing terms.
See `MkTermAntiquote_Tests.thy` for examples and tests.

ML-file *mkterm-antiquote.ML*

end
mk-term: ML antiquotation for building and splicing terms.

theory *MkTermAntiquote-Tests*
imports
MkTermAntiquote
Main
begin

Basic usage: @{*mk-term pattern...* (*vars*, ...)} (*args*, ...)
The vars should match schematic vars in the pattern, and they are substituted with the given arguments.
Template vars can include type vars, and they should be applied to type arguments.

ML-val ‹
@{*assert*} (@{*mk-term ?x* (*x*)} @{*term x*::'*a*}
= @{*term x*::'*a*});

@{*assert*} (@{*mk-term 0*::'*a*::*zero* ('*a*)} @{*typ nat*}
= @{*term 0*::*nat*});

(∗ *Tuples are used to pass multiple arguments* ∗)
@{*assert*} (@{*mk-term ?xs* @ *?ys* (*ys*, *xs*)} (@{*term* [*True*]}, @{*term* [*False*]})

```
        = @{term [False] @ [True]});
›
```

Note that *mk-term* does not perform full type inference automatically. If some argument types are mismatched or too general, the output may be inconsistent. This may change in future versions.

ML-val ‹
```
@{assert} (@{mk-term ?x = ?y (x, y)} (@{term 0::'a::zero}, @{term Suc 0})
        = (Const (@{const-name HOL.eq}, @{typ 'a::zero ⇒ 'a ⇒ bool}) $
            @{term 0::'a::zero} $ @{term Suc 0}))
›
```

Besides static checking, using *mk-term* also gives a reusable template:

ML-val ‹
```
let
  val mk-pair: term*term -> term = @{mk-term (?a, ?b) (a, b)};
in
  @{assert} (mk-pair (@{term ()}, @{term True}) = @{term ((), True)});
  @{assert} (mk-pair (@{term int 1}, @{term int 2})
          = @{term (int 1, int 2)})
end;
›
```

end

3.2 Term pattern: *term-pat*

theory *TermPatternAntiquote* **imports**
  Pure
begin

term-pat: ML antiquotation for pattern matching on terms.
See `TermPatternAntiquote_Tests.thy` for examples and tests.

ML ‹
```
structure Term-Pattern-Antiquote = struct

val quote-string = quote

(* typ matching; doesn't support matching on named TVars.
 * This is because each TVar is likely to appear many times in the pattern. *)
fun gen-typ-pattern (TVar -) = -

  | gen-term-pattern (t as f $ x) =
      (* (read-term-pattern -) helpfully generates a dummy var that is
       * applied to all bound vars in scope. We go back and remove them. *)
      let fun default () = ( ^ gen-term-pattern f ^ $  ^ gen-term-pattern x ^ );
      in case strip-comb t of
            (h as Var ((-dummy-, -), -), bs) =>
              if forall is-Bound bs then gen-term-pattern h else default ()
          | - => default () end
  | gen-term-pattern (Abs (-, typ, t)) =
      Term.Abs (-,  ^ gen-typ-pattern typ ^ ,  ^ gen-term-pattern t ^ )
  | gen-term-pattern (Bound n) = Bound  ^ string-of-int n

(* Create term pattern. All Var names must be distinct in order to generate ML
variables. *)
fun term-pattern-antiquote ctxt s =
  let val pat = Proof-Context.read-term-pattern ctxt s
      val add-var-names' = fold-aterms (fn Var (v, -) => curry (::) v | - => I);
      val vars = add-var-names' pat [] |> filter (fn (n, -) => n <> -dummy-)
      val - = if vars = distinct (=) vars then () else
              raise TERM (Pattern contains duplicate vars, [pat])
  in ( ^ gen-term-pattern pat ^ ) end

end;
val - = Context.>> (Context.map-theory (
    ML-Antiquotation.inline @{binding term-pat}
      ((Args.context -- Scan.lift Parse.embedded-inner-syntax)
        >> uncurry Term-Pattern-Antiquote.term-pattern-antiquote)))
›

end

theory TermPatternAntiquote-Tests
imports
  TermPatternAntiquote
  Main
begin

    Term pattern matching utility.
    Instead of writing monstrosities such as
```

```
case t of
  Const ("Pure.imp", _) $
    P $
    Const (@{const_name Trueprop}, _) $
      (Const ("HOL.eq", _) $
        (Const (@{const_name "my_func"}, _) $ x) $ y)
  => (P, x, y)
```

simply use a term pattern with variables:

```
case t of
  @{term_pat "PROP ?P \<Longrightarrow> my_func ?x = ?y"}
=> (P, x, y)
```

Each *term-pat* generates an ML pattern that can be used in any case-expression or name binding. The ML pattern matches directly on the term datatype; it does not perform matching in the Isabelle logic.

Schematic variables in the pattern generate ML variables. The variables must obey ML's pattern matching rules, i.e. each can appear only once.

Due to the difficulty of enforcing this rule for type variables, schematic type variables are ignored and not checked.

Example: evaluate arithmetic expressions in ML.

ML-val ‹
fun eval-num @{*term-pat numeral ?n*} = *HOLogic.dest-numeral n*
  | *eval-num* @{*term-pat Suc ?n*} = *eval-num n* + *1*
  | *eval-num* @{*term-pat 0*} = *0*
  | *eval-num* @{*term-pat 1*} = *1*
  | *eval-num* @{*term-pat ?x* + *?y*} = *eval-num x* + *eval-num y*
  | *eval-num* @{*term-pat ?x* − *?y*} = *eval-num x* − *eval-num y*
  | *eval-num* @{*term-pat ?x* ∗ *?y*} = *eval-num x* ∗ *eval-num y*
  | *eval-num* @{*term-pat ?x div ?y*} = *eval-num x div eval-num y*
  | *eval-num t* = *raise TERM* (*eval-num*, [*t*]);

›
```

The antiquotation yields a function that matches the schematic variables of a pattern with a `cterm`. The matched parts are returned as `cterm` in a record, where the field name is derived from the original schematic variable name. Moreover a function *instantiate* is returned that can be used to instantiate the matched pattern with other `cterm`s.

The antiquotation makes use of the kernel operations `Thm.match` / `Thm.first_order_match`. These operations are efficient in the sense that no costly re-certification of subterms has to be performed.

ML-val ‹
```
val {f, g, instantiate, ct-} = @{cterm-match λx. ?f x + ?g x} @{cterm λx. p x +
q x}
val twisted = instantiate {f = g, g = f}
```
›

Dummy pattern can also be supplied. The matched values for the dummy patterns are not part of the matching result but still considered in *instantiate*.

ML-val ‹
```
val {f, g, instantiate, ...} = @{cterm-match λx. ?f x + ?g x + -} @{cterm λx. p
x + q + r x}
val twisted = instantiate {f = g, g = f}
```

ML-val ‹
```
val {f, g, ...} = @{cterm-match λx. ?f x + ?g x} @{cterm λx. p x + q}
```
›

ML-val ‹

```
val {f1, f2, ...} = @{cterm-match λx. ?f1.0 x + ?f2.0 x} @{cterm λx. p x + q}
›
```

ML-val ‹
```
val {f, ...} = @{cterm-match λx. ?f x} @{cterm ‹λx. f›}
```
›

There is also a variant for first-order-matching.

ML-val ‹
```
let
  val - = @{cterm-match (fo) λx. ?f x} @{cterm ‹λx. f›}
in
  ()
end
handle Pattern.MATCH => tracing (this is not first order)
```
›

There is also the corresponding antiquotations for plain terms.

ML-val ‹
```
val {f, g, instantiate, ...} = @{match λx. ?f x + ?g x} @{theory} @{term λx. p x
+ q x}
val twisted = instantiate {f = g, g = f}
```
›

There you can also see the different workings of first-order-matching. Note the eta expanded match result in the higher-order variant before.

ML-val ‹
```
val {f, g, instantiate, ...} = @{match (fo) λx. ?f x + ?g x} @{theory} @{term λx.
p x + q x}
val twisted = instantiate {f = g, g = f}
```
›

There is a variant for ML-pattern-matching. This means, that before using first-order-matching it is tested whether the term actually matches the underlying ML-pattern with ML-pattern matching.

ML-val ‹
```
val {f, g, instantiate, ...} = @{cterm-match (ml) λx. ?f x + ?g x} @{cterm λx. p
x + q x}
val twisted = instantiate {f = g, g = f}
```
›

Note that as with all ML-Patterns a variable might only appear once. So the following example is a valid first-order or higher-order pattern but not a valid ML-pattern

ML-val ‹
```
val {f, ...} = @{cterm-match ?f + ?f} @{cterm a + a}
```
›

This is what happens conceptually in the expanded antiquotation.

ML-val ‹
val ctxt = @{context}
val pat = Proof-Context.read-term-pattern ctxt λx. ?f x + ?g x |> Thm.cterm-of ctxt
val [g-var, f-var] = Term.add-vars (Thm.term-of pat) [] |> map (Thm.cterm-of ctxt o Var)
val env = Thm.match (pat, @{cterm λx. a x + b})
val [f, g] = map (Thm.instantiate-cterm env) [f-var, g-var]
val tenv = fst env
val [f-var, g-var] = map (Thm.instantiate-cterm (tenv, Vars.empty)) [f-var, g-var]
fun instantiate {f, g} =
Match-Cterm.cterm-instantiate Position.none env [f-var, g-var] [f, g]
val res = {f = f, g = g, instantiate = instantiate}
val x= instantiate {f=g, g=f}
›

With the verbose flag you can see the generated function.

declare [[*verbose=5*]]

3.4 Record Antiquotation

theory *ML-Record-Antiquotation*
imports *Main*
begin

3.4.1 Motivation

A shortcoming of ML records is the lack of proper update / map functions for the record fields. Manually defining those update functions is considered as painful, as it requires 'quadratic' editing when adding a new field: - add the new field to every record pattern (in every already defined update / map function) - add a new update / map function for the field.

Various workarounds have been proposed. E.g. - Using mutable references as fields to allow for destructive updates - Fancy higher order function-combinators (Fold): http://mlton.org/FunctionalRecordUpdate

Here we develop yet another solution. We provide a ML-Antiquotation that generates the definitions.

For a record specification as datatype `datatype 'a foo = Foo {f1:'a, f2:bool}` it generates the datatype as specified with one constructor `Foo` wrapping the record and additionally all the 'canonical' functions:

- `make_foo`
- `dest_foo`
- `get_f1`
- `get_f2`
- `map_f1`
- `map_f2`

3.4.2 Example

ML-val ‹
datatype 'a *foo* = *Foo of* {*f1*:'a, *f2*:*bool*};

val make-foo = *Foo*;
fun dest-foo (*Foo r*) = *r*;

fun get-f1 (*Foo r*) = #*f1 r*;
fun get-f2 (*Foo r*) = #*f2 r*;

fun map-f1 f (*Foo* {*f1*, *f2*}) =
  Foo {*f1* = *f f1*, *f2* = *f2*};
fun map-f2 f (*Foo* {*f1*, *f2*}) =
  Foo {*f1* = *f1*, *f2* = *f f2*};
›

3.4.3 Implementation

ML ‹

```
structure ML-Record-Antiquotation =
struct

fun remove-comments s =
  let
    val unbalanced-comments-msg = unbalanced ML comments (* ... *)
    fun err-unbalanced () = error unbalanced-comments-msg

    fun rem n [] = if n = 0 then [] else err-unbalanced ()
      | rem n ((::*::)xs) = rem (n + 1) xs
      | rem n (*::)::xs) = if n > 0 then rem (n - 1) xs else err-unbalanced ()
      | rem n (x::xs) = if n = 0 then x::rem n xs else rem n xs
  in

    val maps = mk-maps constr fields;
    fun cond-cons P a xs = if P then a::xs else xs
  in
    cat-lines (cond-cons add-decl decl [make, dest, gets, maps])
  end

end
›
```

Test the parser and its output.

ML-val ‹
```
let
```

```
  val test = datatype 'a foo = Foo of {fld1:int, fld2:'a}
in writeln (ML-Record-Antiquotation.mk-record-datatype-declaration true test) end
›
```

setup ‹
```
ML-Antiquotation.inline-embedded (Binding.make (record,here))
  (Scan.lift Parse.embedded-input >> (fn source =>
    let
      val - = ML-Lex.read-source source; — provide some markup as side effect
       val sanitized-str = fst (Input.source-content source) |> ML-Lex.tokenize |>
ML-Lex.flatten
     in ML-Record-Antiquotation.mk-record-datatype-declaration true sanitized-str
end))
›
```

3.4.4 Examples

ML-val ‹
```
structure JustAStruct = struct
datatype bar = Bar of int;

@{record ‹datatype 'a foo =
  Foo of {f1:'a (* comments are removed *),
  f2:bar }
›}

val my-foo = Foo {f1 = 1, f2 = Bar 42};
val my-foo1 = map-f1 (K (Bar 44)) my-foo;
val t = get-f1 my-foo1

val t1 = make-foo {f1=3, f2=Bar 4}
val t2 = dest-foo t1

@{record ‹datatype foo2 = Foo2 of {f3:int foo}›}

end
›
```

Note that the markup of the datatype declaration is limited to basic Lex-markup. Experiments with explicitly evaluating the datatype with e.g. the `ML` function failed. The issue there is that the `ML` function is not evaluated at the point (aka context) exactly in the text position, but with the context of the surrounding ML command.

The following examples try to illustrate the issues.

Works as expected, as every type referred to in the datatype spec is already known at the beginnig of the **ML-val** command.

ML-val ‹

val - = ML ‹datatype foo = Foo of int›;
›

The following fails as 'bar' is not known at the beginning of the context.

ML-val ‹
datatype bar = Bar of int
val - = ML ‹datatype foo = Foo of bar›
handle ERROR x => warning x
›

Adding a semicolon after the definition of bar helps. There the semicolon marks the end of an "evaluation / compilation chunk". So `ML` is evaluated within an already augmented ML-context that knows about *bar*.

ML-val ‹
datatype bar = Bar of int;
val - = ML ‹datatype foo = Foo of bar›
›

In the context of a structure the semicolon is not enough.

ML-val ‹

structure InAStruct =
struct
datatype bar = Bar of int;

val - = ML ‹datatype foo = Foo of bar›
handle ERROR x => warning x
end

›

end

›
```

3.5.2 Antiquotation for types with schematic variables

```
setup ‹
let
  val parser = Args.context -- Scan.lift Parse.embedded-inner-syntax
  fun typ-pattern (ctxt, str) =
    let
      val ctxt' = Proof-Context.set-mode Proof-Context.mode-schematic ctxt
    in
      str |> Proof-Context.read-typ ctxt'
          |> ML-Syntax.print-typ
          |> ML-Syntax.atomic
    end
in
 ML-Antiquotation.inline @{binding typ-pattern} (parser >> typ-pattern)
end
›

ML ‹@{typ-pattern ?'a list}›
ML ‹Sign.typ-instance @{theory} (@{typ 'a list}, @{typ-pattern ?'a list})›

end
```

Chapter 4

Proof Tools

theory *Tuple-Tools*

imports *Main*
Misc-Antiquotation
TermPatternAntiquote
ML-Fun-Cache

begin

4.1 Tools for handling Tuples

The tools are supposed to help simplifiying expressions containing *case-prod* constructions, like $\lambda(w,\ x,\ y,\ z).\ f\ w\ x\ y\ z$.

- Simprocs for single step splitting and simplification of tuples / *case-prods* instead of repeated application of the built-in variants for pairs
- Looper for the simplifier to instantiate f in $f\ (a,\ b,\ c)$ with $\lambda(a,\ b,\ c).\ g\ a\ b\ c$

4.1.1 Antiquotations for terms with schematic variables

setup ‹
let
val parser = Args.context −− Scan.lift Parse.embedded-inner-syntax
fun pattern (ctxt, str) =
str |> Proof-Context.read-term-pattern ctxt
|> ML-Syntax.print-term
|> ML-Syntax.atomic
in
ML-Antiquotation.inline @{*binding pattern*} (*parser >> pattern*)
end

›

ML ‹@{*pattern* λ(*a*,*b*,*c*). *?g a b c*}›

setup ‹
let
type style = *term* −> *term*;

fun pretty-term-style ctxt (*style*: *style*, *t*) =
  Document-Output.pretty-term ctxt (*style t*);

val basic-entity = *Document-Output.antiquotation-pretty-source*;

in
(∗ *Document antiquotation that allows schematic variables* ∗)
(*basic-entity* ***binding*** ‹*pattern*› (*Term-Style.parse* −− *Args.term-pattern*) *pretty-term-style*)
end
›

Unification only works modulo ordinary beta reduction but does not succeed on tupled-beta reduction. For example the simplifier will not find an instatiation for the variable *?c*

schematic-goal ⋀*a b*. (*case* (*a*, *b*) *of* (*x*, *y*) ⇒ *f x y*) ≡ *?c* (*a*, *b*)
  apply *simp*
  oops

Such equations can typically occur in congruence rules when a pair is splitted by (⋀*x*. *PROP ?P x*) ≡ (⋀*a b*. *PROP ?P* (*a*, *b*)).

lemma *tuple-up-eq-trivial*: *f r* ≡ (λ*x*. *f x*) *r*
  by *simp*

thm *tuple-up-eq-trivial*
lemma *tuple-up-eq2*: *f* (*fst r*) (*snd r*) ≡ (*case r of* (*x1*, *x2*) ⇒ *f x1 x2*)
  by (*simp add*: *split-def*)

Constant to explictly trigger splitting by simproc `SPLIT_simproc` below

definition *SPLIT* :: *'a*::{} ⇒ *'a*
  where *SPLIT P* ≡ *P*

lemma *SPLIT-cong*: *PROP SPLIT P* ≡ *PROP SPLIT P*
  by *simp*

lemma *case-prod-out*: (λ*r*. *f* ((λ(*a*,*b*). (*g a b*)) *r*)) = (λ(*a*, *b*). *f* (*g a b*))
  apply (*rule ext*)
  apply (*simp add*: *split-paired-all*)
  done

lemma *case-prod-eta-contract*: (λ*x*. (*case-prod s*) *x*) ≡ (*case-prod s*)
  by *simp*

definition *ETA-TUPLED* :: $('a \Rightarrow 'b) \Rightarrow ('a \Rightarrow 'b)$
where *ETA-TUPLED f* $\equiv f$

lemma *ETA-TUPLED-trans*: $f \equiv g \Longrightarrow$ *ETA-TUPLED f* $\equiv g$
by (*simp add*: *ETA-TUPLED-def*)

Add the congruence rule *SPLIT PROP ?P* $\equiv$ *SPLIT PROP ?P* to the simpset together with the simproc to avoid descending into P before the split.

(*
 * Generates a custom rule with the tuple arity of an abstracted variable. The
position of the
 * abstraction is specified in the pattern (which is also used as simproc pattern).
Every real variable
 * in that pattern (besides the dummy pattern -) will be considered as an abstraction
to split. E.g.
 * thm: ⋀v. P (?y v) ⟹ seq ?x (λx. ?y x) with pattern seq - ?Y
 * When this is applied to a term seq x (λ(a,b,c). ?y a b c) a rule of arity 3 will be
generated:
 * ⋀a b c. P (?y a b c) ⟹ seq ?x (λ(a, b, c). ?y a b c) which can be matched with
the term.

theory Option-Scanner
imports ML-Record-Antiquotation
begin
```

The purpose of the option scanner is to provide an interface to scan lists of options (key / value) for toplevel commands. As values may have different types the idea is that the collection of options is represented by an record of optional values. This record can be provided individually for each command. The initial option-record "empty" has every component assigned to `NONE`. To be able to specify all options in a single list, we represent a single parser / scanner for a field as an update function for the option-record, which is composed by the map-functions for the record fields. So we can preserve different types for parsing individual fields (and do not need an universal value type), while the specification list is a monotype.

```

  in SIMPLE-METHOD tac [] end)
›
```

```
method repeat-new methods m = (m ; (repeat-new ‹m›)?)
```

The following *fails* and *succeeds* methods protect the goal from the effect of a method, instead simply determining whether or not it can be applied to the current goal. The *fails* method inverts success, only succeeding if the given method would fail.

```
method-setup fails =
‹Method.text-closure >> (fn m => fn ctxt => fn facts =>
  let
    fun fail-tac st' =
      (case Seq.pull (method-evaluate m ctxt facts st') of
         SOME - => Seq.empty
       | NONE => Seq.single st')

  in SIMPLE-METHOD fail-tac facts end)
›
```

```
method-setup succeeds =
```

```
‹Method.text-closure >> (fn m => fn ctxt => fn facts =>
  let
    fun can-tac st' =
      (case Seq.pull (method-evaluate m ctxt facts st') of
         SOME (st'',-) => Seq.single st'
       | NONE => Seq.empty)

  in SIMPLE-METHOD can-tac facts end)
›
```

This method wraps up the "focus" mechanic of match without actually doing any matching. We need to consider whether or not there are any assumptions in the goal, as premise matching fails if there are none.

If the *fails* method is removed here, then backtracking will produce a set of invalid results, where only the conclusion is focused despite the presence of subgoal premises.

```
method focus-concl methods m =
  ((fails ‹erule thin-rl›, match conclusion in - ⇒ ‹m›)
  | match premises (local) in H:- (multi) ⇒ ‹m›)
```

repeat applies a method a specific number of times, like a bounded version of the '+' combinator.

usage: apply (repeat n *text*)

- Applies the method *text* to the current proof state n times. - Fails if *text* can't be applied n times.

```
ML ‹
  fun repeat-tac count tactic =
    if count = 0
    then all-tac
    else tactic THEN (repeat-tac (count − 1) tactic)
›

method-setup repeat = ‹
  Scan.lift Parse.nat −− Method.text-closure >> (fn (count, text) => fn ctxt =>
fn facts =>
    let val tactic = method-evaluate text ctxt facts
    in SIMPLE-METHOD (repeat-tac count tactic) facts end)
›

notepad begin
  fix A B C
  assume assms: A B C
```

repeat: simple repeated application.

```
  have A ∧ B ∧ C ∧ True
```

repeat: fails if method can't be applied the specified number of times.

```
    apply (fails ‹repeat 4 ‹rule conjI, rule assms››)
```

apply (*repeat 3* ‹*rule conjI*, *rule assms*›)
by (*rule TrueI*)

repeat: application with subgoals.

have $A \wedge A\ B \wedge B\ C \wedge C$
apply −

We have three subgoals. This *repeat* call consumes two of them.

apply (*repeat 2* ‹*rule conjI*, (*rule assms*)+›)

One subgoal remaining...

apply (*rule conjI*, (*rule assms*)+)
done

end

Literally a copy of the parser for *subgoal-tac* composed with an analogue of **prefer**.

Useful if you find yourself introducing many new facts via *subgoal-tac*, but prefer to prove them immediately rather than after they're used.

```
setup ‹
  Method.setup binding ‹prop-tac›
    (Args.goal-spec -- Scan.lift (Scan.repeat1 Parse.embedded-inner-syntax --
Parse.for-fixes) >>
      (fn (quant, (props, fixes)) => fn ctxt =>
        (SIMPLE-METHOD'' quant
          (EVERY' (map (fn prop => Rule-Insts.subgoal-tac ctxt prop fixes) props)
            THEN'
            (K (prefer-tac 2))))))
    insert prop (dynamic instantiation), introducing prop subgoal first
›

notepad begin {
  fix xs
  assume assms: list-all even (xs :: nat list)

  from assms have even (sum-list xs)
    apply (induct xs)
     apply simp

    Inserts the desired proposition as the current subgoal.

    apply (prop-tac list-all even xs)
     subgoal by simp

    The prop list-all even xs is now available as an assumption. Let's add
another one.

    apply (prop-tac even (sum-list xs))
     subgoal by simp
```

Now that we've proven our introduced props, use them!

```
  apply clarsimp
  done
}
end
```

7.3 Advanced combinators

7.3.1 Protecting goal elements (assumptions or conclusion) from methods

```
context
begin

private definition protect-concl x ≡ ¬ x
private definition protect-false ≡ False

private lemma protect-start: (protect-concl P ⟹ protect-false) ⟹ P
  by (simp add: protect-concl-def protect-false-def) (rule ccontr)

private lemma protect-end: protect-concl P ⟹ P ⟹ protect-false
  by (simp add: protect-concl-def protect-false-def)

method only-asm methods m =
  (match premises in H[thin]:- (multi,cut) ⇒
    ‹rule protect-start,
     match premises in H'[thin]:protect-concl - ⇒
       ‹insert H,m;rule protect-end[OF H']››)

method only-concl methods m = (focus-concl ‹m›)

end

notepad begin
 fix D C
  assume DC:D ⟹ C
  have D ∧ D ⟹ C ∧ C
  apply (only-asm ‹simp›) — stash conclusion before applying method
  apply (only-concl ‹simp add: DC›) — hide premises from method
  by (rule DC)

end
```

7.3.2 Safe subgoal folding (avoids expanding meta-conjuncts)

Isabelle's goal mechanism wants to aggressively expand meta-conjunctions if they are the top-level connective. This means that *fold-subgoals* will immediately be unfolded if there are no common assumptions to lift over.

To avoid this we simply wrap conjunction inside of conjunction' to hide it from the usual facilities.

context begin

definition
conjunction′ :: *prop* ⇒ *prop* ⇒ *prop* (**infixr** ‹&^&› *2*) **where**
conjunction′ A B ≡ (*PROP A* &&& *PROP B*)

In general the context antiquotation does not work in method definitions. Here it is fine because `Conv.top_sweep_conv` is just over-specified to need a Proof.context when anything would do.

method *safe-meta-conjuncts* =
raw-tactic
‹*REPEAT-DETERM*
(*CHANGED-PROP*
(*PRIMITIVE*
(*Conv.gconv-rule* ((*Conv.top-sweep-conv* (*K* (*Conv.rewr-conv* @{*thm conjunction′-def*[*symmetric*]})) @{*context*})) *1*)))›

method *safe-fold-subgoals* = (*fold-subgoals* (*prefix*), *safe-meta-conjuncts*)

lemma *atomize-conj′* [*atomize*]: (*A* &^& *B*) == *Trueprop* (*A* & *B*)
by (*simp add*: *conjunction′-def*, *rule atomize-conj*)

lemma *context-conjunction′I*:
PROP P ⟹ (*PROP P* ⟹ *PROP Q*) ⟹ *PROP P* &^& *PROP Q*
apply (*simp add*: *conjunction′-def*)
apply (*rule conjunctionI*)
apply *assumption*
apply (*erule meta-mp*)
apply *assumption*
done

lemma *conjunction′I*:
PROP P ⟹ *PROP Q* ⟹ *PROP P* &^& *PROP Q*
by (*rule context-conjunction′I*; *simp*)

lemma *conjunction′E*:
assumes *PQ*: *PROP P* &^& *PROP Q*
assumes *PQR*: *PROP P* ⟹ *PROP Q* ⟹ *PROP R*
shows
PROP R
apply (*rule PQR*)
apply (*rule PQ*[*simplified conjunction′-def*, *THEN conjunctionD1*])
by (*rule PQ*[*simplified conjunction′-def*, *THEN conjunctionD2*])

end

notepad begin

fix D C E

assume DC: $D \wedge C$
have D $C \wedge C$
apply $-$
apply (*safe-fold-subgoals*, *simp*, *atomize* (*full*))
apply (*rule DC*)
done

end

7.4 Utility methods

Unified Memory Model (UMM)

11.1 More Word Lemmas

This is a holding area for Word utility lemmas that are too specific or unpolished for the AFP, but which are reusable enough to be collected together for the rest of L4V. New utility lemmas that only prove facts about words should be added here (in preference to being kept where they were first needed).

type-synonym *field-name* = *string*
type-synonym *qualified-field-name* = *field-name list*

type-synonym *typ-name = string*

A *typ-desc* wraps a *typ-struct* with a typ name. A *typ-struct* is either a Scalar, with size, alignment and either a field description (for *typ-info*) or a 'normalisor' (for *typ-uinfo*), or an Aggregate, with a list of *typ-desc*, field name, and field descripton (for the complete sub-structure) or unit (for *typ-uinfo*). The field description for aggregates is an extension of the original work of H. Tuch. It is used to make the construction of a new structure from nested structures / arrays more efficient. Properties like commutation of fields can be expressed and proven for the toplevel fields only, without having to re-examine the nested leafs of the tree.

11.13 Instantiation, inferring type instantiation from term instantiation.

ML-val
‹
instantiate ‹*'a*=***typ*** ‹*nat*› *and* *x*=***term*** ‹*1*::*nat*› *in term* ‹*x + x*› *for* *x*::*'a*::*plus*›
›

This is a variant of of the instantiate antiquotation, e.g.: `\<^instantiate>\<open>'a=\<^typ>\<c`
`and x=\<^term>\<open>1::nat\<close> in term \<open>x + x\<close>`
`for x::\<open>'a::plus\<close>\<close>`.

The instantiate antiquotation requires the explicit instantiation of type-variables, including those that can be inferred from the term instantiation. This makes the code very explicit, predictable and efficient as no types have to be calculated at runtime or be 'guessed' by the reader. On the other hand it can make the resulting code quite verbose when the number of type variables increases.

In this theory we provide a variant, that allows to omit those type-instantiations that are already fixed by the given term instantiations. This follows the same idea as e.g. `Drule.infer_instantiate`.

Moreover, we provide a variant that also takes a morphism into account. The use-case here is that the instantiate expression is written within a locale context but later on is used in an interpretation of the locale (given by morphism phi). Before instantiation the term is exported (according to morphism phi).

```

```
val - = Theory.setup
 (ML-Context.add-antiquotation-embedded binding ‹infer-instantiate› (antiquotation
false) #>
  ML-Context.add-antiquotation-embedded binding ‹morph-infer-instantiate› (antiquotation
true))

in end;

end
›
```

Here an example with explicit instantiation.

```
ML-val ‹
val b = Free(n, typ ‹nat›)
val t1 = instantiate ‹'a = typ ‹nat› and a = ‹@{term 1::nat}› and b=‹b›
     in term  ‹a + b› for a b::'a::plus›
›
```

With the new variant the type instantiation can be omitted as it is already inferred from the term instantiations. Note that the result of the antiquotation is function that expects a `Proof.context`. This is used to perform the necessary type inference and provide context sensitive error messages.

```
ML-val ‹
val b = Free(n, typ ‹nat›)
val t1 = infer-instantiate ‹a =term ‹1::nat› and b=‹b›
     in term  ‹a + b› for a b::'a::plus› @{context}
›
```

This can be shortened:

```
ML-val ‹
val b = Free(n, typ ‹nat›)
val t1 = infer-instantiate ‹a = term ‹1::nat› and b=‹b›
     in term  ‹a + b›› @{context}
›
```

Here is an example were not all type variables can be inferred from the term instantiation. Those types can be explicitly instantiated.

```
ML-val ‹
val t1 = infer-instantiate ‹'b = typ ‹int› and a = ‹@{term 1::nat}›
     in term  ‹Pair a› for a ::'a › @{context}
›

ML-val ‹
val t1 = morph-infer-instantiate ‹'b = typ ‹int› and a = ‹@{term 1::nat}›
     in term  ‹Pair a› for a ::'a › Morphism.identity @{context}
›

ML-val ‹
```

```
val v = Proof-Context.read-term-pattern @{context} v
val t1 = infer-instantiate ‹'b = typ ‹int› and a = v
    in term ‹Pair a› for a ::'a › @{context}
›

ML-val ‹
val v = Proof-Context.read-term-pattern @{context} v::'a::type |> Thm.cterm-of
@{context}
val t1 = infer-instantiate ‹'b = ctyp ‹int› and a = v
    in cterm ‹Pair a› for a ::'a › @{context}
›

ML-val ‹
val t1 = infer-instantiate ‹'b = ctyp ‹int› and a = ‹@{cterm 1::nat}›
    in cterm ‹Pair a› for a ::'a › @{context}
›

context
  fixes x::'a::plus
begin
ML-val ‹
val b = Free(n, typ ‹nat›)
val t1 = infer-instantiate ‹a = ‹@{term 1::nat}› and b=‹b›
in term ‹a + b› for a b› @{context}
›
end
```

Note that the antiquotation only makes some local type-inference on the term parameters alone. There might be further use cases to perform a type inference on the whole term instead. This might be further fine-tuned by inserting explicit dummy types to be inferred: -.

```
ML ‹
fun infer-types-simple ctxt =
   singleton (Type-Infer-Context.infer-types-finished ctxt);

val b = Free(n, dummyT)
val t1 = instantiate ‹'a = typ ‹-› and a = ‹@{term 1::nat}› and b=‹b›
in prop ‹a + b = a + b› for a b::'a::plus › |> infer-types-simple @{context}
›

end
```

This expresses "disjointness" on scenes, saying that two scenes occupy disjnt parts of the type.

It is stronger than "commutativity" $\forall\ a\ c.$ *m1 a* (*m2 a b*) = *m2 a* (*m1 a b*) which is enough to show composition, but in our cases we are interested in disjointness. Important difference: a scene *m* "commutes" with itself, but only $\lambda a.$ *id* is disjoint with itself.

11.20 More properties of maps plus map disjuction.

theory *MapExtra*
imports *Main*
begin

BEWARE: we are not interested in using the $dom\ x \cap dom\ y = \{\}$ rules from Map for our separation logic proofs. As such, we overwrite the Map rules where that form of disjointness is in the assumption conflicts with a name we want to use with $\bot$.

A note on naming: Anything not involving heap disjuction can potentially be incorporated directly into Map.thy, thus uses m. Anything involving heap disjunction is not really mergeable with Map, is destined for use in separation logic, and hence uses h

---

lemma *map-add-disj'*:
$(h_1 ++ h_2) \perp h_0 = (h_1 \perp h_0 \wedge h_2 \perp h_0)$
by (*simp add*: *map-disj-def*, *fast*)

We redefine (++) associativity to bind to the right, which seems to

be the more common case. Note that when a theory includes Map again, *map-add-assoc* will return to the simpset and will cause infinite loops if its symmetric counterpart is added (e.g. via *map-ac-simps*)

declare *map-add-assoc* [*simp del*]

Since the associativity-commutativity of (++) relies on map disjunction, we include some basic rules into the ac set.

Like in Separation.thy, these arrows are defined using bsub and esub but have an *input* syntax abbreviation with just sub. Why? Because if sub is the only way, people write things like $p \mapsto^i_{(f\ x\ y)}\ v$ instead of $p \mapsto^i_{(f\ x\ y)}$

v. We preserve the sub syntax though, because esub and bsub are a pain to type.

Derived from *array-assertion*, an appropriate assertion for performing a pointer addition, or for dereferencing a pointer addition (the strong case).

In either case, there must be an array connecting the two ends of the pointer transition, with the caveat that the last address can be just out of the array if the pointer is not dereferenced, thus the strong/weak distinction.

If the pointer doesn't actually move, nothing is learned.

Note that the C-Parser associates sequential composition to the right. So the first statement is typically already an 'atomic' statement (or at least no further sequential composition) that can be solved. We place it as the second precondition because the modifies-tactic follows the canonical order of tactical reasoning and solves the subgoals from the back. So *c1* is already solved before further decomposing *c2*. This keeps the number of subgoals (and thus the overall goal-state) small.

We integrate mllex and mlyacc directly into Isabelle:

- We compile the SML files according to the description in `tools/mlyacc/src/FILES`
- We export the necessary signatures and structures to the Isabelle/ML environment.
- As mllex / mlyacc operate directly on files we invoke them on temporary files and redirect stdout / stderr to display the messages within PIDE. We wrap this in Isabelle commands **mllex**, **mlyacc**.

Simple congruence prover
Replaces a goal of the shape:
f x (*g y*) (λ*x*. *x* + *1*) = *f x'* (*i y'*) (λ*z*. *z* + *Suc 0*)
by
x = *x' g y* = *i y' 1* = *Suc 0*
The tactic essentially applies ⟦*?f* = *?g*; *?x* = *?y*⟧ ⟹ *?f ?x* = *?g ?y*, but using first-order matching.

16.4 *post-state* type

datatype *'r post-state* = *Failure* | *Success 'r set*

Failure is supposed to model things like undefined behaviour in C. We usually have to show the absence of *Failure* for all possible executions of the program. Moreover, it is used to model the 'result' of a non terminating computation.
